1. Generalities.
About 10 years ago a book [1] has been edited in honour of
Nikolai N. Bogolubov.

In this book F. Baumann and R. Jost described their work on
an entropy inequality, the so-called strong subadditivity
property conjectured by O.E. Lanford, D. Robinson, and D. Ruelle
[2], [3], and on the Yanase-Wigner-Dyson conjecture. E. Lieb [4]
was the first, partially together with B. Ruskai [5], who was able
to solve both problems which, indeed, are connected one-to-another.
Thus, I could add only two further variants of proving this.
One [6] makes use of the concavity of $A \to \text{Tr. exp} (B + \ln A)$
discovered by E. Lieb [4] and H. Epstein [7], the other
variant relies on an interpolation theory [8] based on an
observation of W. Pusz and S. L. Woronowicz [9]. In trying to
analyse the strong subadditivity conjecture in the quantum case
( - it is almost trivial for classical discrete distributions - ),
as a by-product, the order structure of states [10] appeared,
a tool to describe some aspects of irreversibility (though not
the very problem of irreversibility).
In asking about differences in the general properties of entropy in classical and in quantum physics one finds astonishingly only very few. Indeed, at the first glance the main difference is in the much harder proofs of the quantum entropy properties. But there is (at least) one striking difference between classical and quantum entropy: the failure of monotonicity for the latter (see [11], [12]).

Though mathematically rather simple, if not trivial, it is physically remarkable: The entropy of a subsystem can be strictly larger than the entropy of the total system!

One does not mention, usually, this fact for several reasons. At first, in characterizing subsystems by spatial separation and then performing the thermodynamical limit, the entropy (per volume) becomes additive and monotonicity holds. Secondly, monotonicity can be destroyed only if the observables characterizing the total system do not commute with those of the subsystem.

This may well be compared with a measurement in the sense of von Neumann. To recognize something as a subsystem of a total system "reduction" of the density matrix. This reduction is accompanied by an extra increase in entropy. This extra increase can overcompensate the usual decrease we have in situations equivalent with classical ones.

In view of the non-monotonicity of quantum entropy it is important and really not self-evident that most of the properties of entropy known in classical statistics remain valid in the quantum case also.

In the following we shortly discuss some of those properties of entropy which have been under investigation in the last decade. We restrict ourselves to the technical simplest possible assumptions, i.e. we handle only finite-dimensional density matrices,
Hilbert spaces,... Some more complete discussions are given in W. Thirring [13] and A. Wehrl [12].

2. Systems and Subsystems, states and reduced states.
Let us assume (for simplicity) that the observables of a certain physical system can be chosen as the set of Hermitian n-by-n-matrices. We then call the matrix algebra $\mathbb{M}_n$ of all n-by-n-matrices the "algebra of observables".
A "state", $\omega$, is uniquely determined by the family of expectation values, $\omega(A)$, where $A \in \mathbb{M}_n$ is any matrix.
One requires linearity in $A \rightarrow \omega(A)$, $\omega(A) \geq 0$ if $A \geq 0$ (positivity), and the normalization $\omega(E) = 1$ with the unity matrix $E$. These requirements are satisfied if and only if there is with a density matrix $\omega$

$$\omega(A) = \text{Tr} \cdot \omega \cdot A \quad \text{for all } A \quad (1)$$

(We use the same symbol for the state functional $A \rightarrow \omega(A)$ and its density matrix. Let us recall that a density matrix is a positive semidefinite matrix of trace one.)

$\mathbb{M}_n$ can be considered as the algebra $\mathbb{B}(\mathbb{H})$ of linear operators acting on a n-dimensional Hilbert space $\mathbb{H}$. If then $x \in \mathbb{H}$ is a normed vector, it defines a pure state $A \rightarrow \pi(A) = (x, Ax)$. If $\pi$ is the projection operator from $\mathbb{H}$ onto the subspace spanned by $x$ we have $(x, Ax) = \text{Tr} \cdot \pi \cdot A$ and $\pi$ is a density matrix. As it is known a density matrix $\pi$ represents a pure state iff it is a one-dimensional projection.

One of the most satisfying ways to define "subsystems" is by observables. We have to select all those observables of the total system which do not discriminate outside the subsystem.
Clearly, a state of the subsystem should be characterized by
its expectation values with respect to these observables.
A correct and sufficiently general definition is to associate
the concept of a subsystem with that of an algebra of observ-
ables which is a subalgebra $\mathcal{A}$ of the algebra $\mathbb{M}_n$. For the
possibility of a correct interpretation the subalgebra $\mathcal{A}$
should fulfil two conditions: $A \in \mathcal{A}$ should imply $A^* \in \mathcal{A}$,
and $E \in \mathcal{A}$ where $E$ is the unit element of $\mathbb{M}_n$.
Every linear, positive, and normed functional on $\mathcal{A}$ is called
"state of $\mathcal{A}$", i.e. state of the subsytem under consideration.
If we have a state of $\mathbb{M}_n$ i.e. of our total system, then its
restriction onto $\mathcal{A}$ is called the state reduced to the sub-
system given by $\mathcal{A}$.
The subalgebras in question are well known in its structure.
We shall consider here only those which are themselves isomorphic
to full matrix algebras. This is the case if and only if the
centre of $\mathcal{A}$ consists of the multiples of the unit element only
("trivial centre"). Technically, $\mathcal{A}$ is then called a factor.
Let $\mathcal{A}$ be a factor of $\mathbb{M}_n \cong B(\mathcal{H})$. Then there is a decompo-
sition $\mathcal{H} = \mathcal{H}_1 \otimes \mathcal{H}_2$ such that $\mathcal{A}$ consists of all matrices
(operators) of the form $A_1 \otimes E_2$ where $A_1$ acts on $\mathcal{H}_1$, $E_2$
is the identity on $\mathcal{H}_2$ and $\otimes$ is the (Kronecker) tensor
product. If we change the role of $\mathcal{H}_1$ and $\mathcal{H}_2$ we get again
a factor. It is denoted by $\mathcal{A}'$ and consists of all those ma-
trices of $\mathbb{M}_n$ which commute with every matrix of $\mathcal{A}$. $\mathcal{A}'$
describes the subsystem orthogonal to $\mathcal{A}$.
Let now $\omega$ be a state of $\mathbb{M}_n$ and $\omega_{\mathcal{A}}$ its reduction onto $\mathcal{A}$.
Then
$$A_1 \rightarrow \omega_{\mathcal{A}}(A_1 \otimes E_2) = \omega(A_1 \otimes E_2), \quad A_1 \in B(\mathcal{H}_1) \quad (2)$$
is a state of $B(\mathcal{H}_1)$ and hence given by a density matrix $\omega_1$.
$\omega_1$ is usually called reduced density matrix.
Sometimes it is useful to lift the reduced density matrix to a density matrix of the total system such that it carries as few as possible information about the subsystem given by $\mathfrak{A}'$. This is done by the map

$$\omega \rightarrow T_\mathfrak{A} \omega = (1/n_2) \omega_1 \otimes E_2$$

(3)

where $n_2$ is the dimension of $\mathbb{H}_2$. The right hand side of (3) can be obtained by invariant integration of $U^{-1} \omega U$ over the group of unitary matrices contained in $\mathfrak{A}'$. Let us now assume $x_1, x_2, \ldots$ and $y_1, y_2, \ldots$ denote complete orthonormal systems of $\mathbb{H}_1$ and $\mathbb{H}_2$ respectively. The reduced density matrices $\omega_1, \omega_2$ of both subsystems considered with respect to the pure state $\mathcal{X}$ characterized by the vector

$$\sum c_{ik} x_i \otimes y_k$$

(4a)

have matrix elements with respect to the orthonormal systems

$$i,j \rightarrow \sum_{k} c_{ik} \bar{c}_{jk} \quad \text{and} \quad k,l \rightarrow \sum_{i} c_{ik} \bar{c}_{il}$$

(4b)

Here we see explicitly the reason for the non-monotonicity of entropy: If $\dim \mathbb{H}_1 > \dim \mathbb{H}_2$, every state of $\mathfrak{A}$ can be obtained by reducing a suitable pure state of the total system to the given subsystem! In classical statistics, in contrast to this, a pure state always reduces to pure states in subsystems.

There is, of course, no "total system" in Nature. Every system can be considered as a subsystem of another larger or more detailed described system. (Feynman in his "lectures" remarked: "But it is true that if we look at a glass of wine closely enough we see the entire universe.") Hence the concept of pureness of a state entirely relates to a given observable algebra. By enlarging a system, by a more detailed analysis,
a mixed state (mixture a la von Neumann and Gibbs) can become a pure one and vice versa.

Unfortunately, the connection of this peculiarity (and of similar ones) of quantum statistics to the phenomenon of irreversibility is not yet fully analysed.

3. Entropy.

Entropy is a state functional of the following type: Let \( s \rightarrow f(s) \) denote a real-valued function on the unit interval and define

\[
S_f(\omega) = k_B \text{Tr}.f(\omega) \tag{5}
\]

\((k_B\) is Boltzmann's constant.) In the case \( f(s) = -s \ln s \) we write simply \( S(\omega) \) and call it "entropy of \( \omega \)."

There is a more intrinsic definition for \( S \) and, more general, for \( S_f \) if \( f'' \leq 0 \) (concavity), which applies for all (here finite dimensional) algebras \( \mathcal{A} \): The set of all states of \( \mathcal{A} \) is naturally a convex set with respect to the performing of mixtures. Its extremal elements are called "pure states". (For \( \mathbb{M}_n \) this is a statement, for general \( \mathcal{A} \) it is a definition.)

Now \( S_f(\omega) \) is the infimum of all numbers \( k_B \sum f(c_j) \) where the sequences \( c_1, c_2, \ldots \) runs over all possibilities to get \( \omega = \sum c_i \mathcal{X}_i \) with \( c_i > 0 \) and suitably chosen pure states \( \mathcal{X}_i \).

The entropy of a state is zero iff it is a pure state. Because we can get pure states after enlarging a given system, entropy does not necessarily shows monotonicity in going from a system to a subsystem or vice versa.

A very usual example is the observation of one peculiar atom in a molecule, the molecule being in its ground state. The reduced density matrix of the atom observed is highly mixed. Exotic ex-
amples are (i) the remark of Lieb [11] that the entropy of every (meta-)galaxis may steadily increase though the universum's total entropy remain zero and (ii) the absorption (going beyond the horizon of forgetting of a black hole) of one component of a particle-antiparticle system originally in a pure state. If the body is in a Gibbsian canonical state then the escaping particle is in a Gibbsian canonical ensemble of the same temperature as the body is (Hawkin).

These affairs are controlled by some inequalities which, apart from some finer technical points, characterize $S$ uniquely within the state functional (not only within all $S_{\omega}$). If we consider $\hat{A}$ and $\hat{A}'$ of $M_n$ belonging to a decomposition $H = H_1 \otimes H_2$, a state $\omega$ and its reductions $\omega_1$ and $\omega_2$ to $\hat{A}$ and $\hat{A}'$ accordingly, we have

$$S(\omega) \leq S(\omega_1) + S(\omega_2) \quad \text{subadditivity}$$

(6)

$$\text{triangle inequality:} \quad |S(\omega_1) - S(\omega_2)| \leq S(\omega) \quad (7)$$

Subadditivity is long and well known, but (7) is discovered by Araki and Lieb [14].

The already mentioned strong subadditivity is a considerable sharpening of (6). Here we consider the case $H = H_1 \otimes H_2 \otimes H_3$ and the corresponding to $H_j$ factors $\hat{A}_j$. For any permutation $(i,j,k)$ of the integers $(1,2,3)$ the factor $\hat{A}_{ijk}$ corresponding to $H_{ijk}$ satisfies $\hat{A}_{ijk} = \hat{A}_1' = \hat{A}_j \otimes \hat{A}_k$. The reduction of a state $\omega$ onto a subsystem $\hat{A}_1$ or $\hat{A}_{jk}$ is denoted by $\omega_1$ and $\omega_{jk}$ strong subadditivity may then be expressed by

$$S(\omega) + S(\omega_1) \leq S(\omega_{1k}) + S(\omega_{1j}) \quad (8)$$

One proof of (8) can be sketched as follows: We at first notice that (3) implies $S(T_{\hat{A}}(\omega)) = S(\omega_1) + \ln n_2$. 

Denoting by $T_i$, $T_{jk}$, the maps corresponding to the factors $A_i$, $A_{jk}$, one easily finds the equivalence of (8) with

$$S(\omega) + S(T_i \omega) \leq S(T_{ik} \omega) + S(T_{ij} \omega)$$  \hspace{1cm} (8a)

because the logarithmic terms cancel.

This inequality can be handled directly by the Epstein-Lieb result mentioned in §1. Another way is to introduce Umegaki's relative entropy $S(\varphi, \omega) = \text{Tr.} (\omega \ln \omega - \omega \ln \varphi)$ and to mention the nice relation

$$S( T_{ik} \omega, \omega) = -S(\omega) + S(T_{ik} \omega)$$  \hspace{1cm} (9)

Now one finds $T_{ij} T_{ik} = T_i$ and we are done if we could prove for $T = T_{ij}$ and $\varphi = T_{ik} \omega$ the general relation

$$S(\varphi, \omega) \geq S(T \varphi, T \omega)$$  \hspace{1cm} (10)

for a class of maps $T$ which contain $T_{ik}$.

(10) is true for all maps of the form $\left( t_j > 0, \sum t_i = 1 \right)$

$$\varphi \rightarrow T \varphi = \sum t_i U_i \varphi U_i^{-1}, \ U_j \text{ unitary}$$  \hspace{1cm} (11)

to which set the map $T_{ik}$ belongs. The proof is by noting

$$S(\varphi, \omega) = - (d/ds)_{s=0} \text{Tr.} \omega^{1-s} \varphi^s$$  \hspace{1cm} (12)

and proving the assertion for $\text{Tr.} \omega^{1-s} \varphi^s$.

The latter statement, however, is a consequence of Lieb's concavity theorem [4] for $\left( 0 < s < 1 \right)$

$$\varphi, \omega \rightarrow \text{Tr.} x^* \omega^{1-s} x \varphi^s$$  \hspace{1cm} (13)

Lieb has shown his theorem by analytical interpolation. Another interpolation theory [8] shows the validity of (10) and the corresponding inequality for the functional (13) for every map $T$ which is linear, and chaos enhancing (see below), and for which $T^*$ fulfils a Kadison inequality.
4. The order structure of states.

Some properties of entropy are shared by many other state functionals: Let \( f'' \leq 0 \), \( t_i \geq 0 \), \( \sum t_j = 1 \). Then for arbitrary chosen states we have

\[
S_f(\sum t_i \Omega_i) \geq \sum t_j S_f(\Omega_j)
\]

which is complemented by

\[
\sum S_f(t_i \Omega_i) \geq S_f(\sum t_j \Omega_j)
\]

According to (14) every \( S_f \) is increasing in the "direction" of performing Gibbs-von Neumann mixtures - but every \( S_f \) does this in its own way. To get rid of this arbitrariness one considers a partial order within the set of all states, the "order structure" of states \([10] , [12] , [13]\) in defining

\[
\Omega \preceq \Omega \text{ iff } S_f(\Omega) \geq S_f(\Omega) \text{ for all } f'' \leq 0
\]

Verbally, \( \Omega \preceq \Omega \) is expressed by saying \( \omega \) is **more chaotic** (or "more mixed", or "less pure") than \( \Omega \).

A map \( T \) is called **chaos enhancing** if always \( T \Omega \preceq \Omega \).

Every map (3) is of that kind. Other examples are described in the quoted literature.

Generally, \( \preceq \) characterizes relaxations, diffusions and other processes which point, in a very strict sense, "in the direction of irreversibility".

The mathematical technique will be described in \([15]\).
